**Abstract.** Periosteal osteosarcoma (POS) is a rare primary malignant bone tumor arising from the surface of long bones. In addition, Marfan’s syndrome (MFS) is an infrequent hereditary autosomal dominant connective tissue disorder with high penetrance and variable phenotypes, which primarily affects the ocular, skeletal and cardiovascular systems. The present study reported a case of POS and MFS co-occurring in a child. A 6-year-old girl with MFS presented with pain, swelling and deformity in the right thigh following a fall. The patient was diagnosed with a right femoral shaft fracture and underwent open internal fixation surgery at a local hospital. At 2 weeks following surgery, the patient's parents observed increased swelling in the right thigh and thus, revisited the clinic. X-ray examination revealed extensive osteotylus around the fracture site and the clinician decided to remove the internal fixation. Following removal of the implant, aggravated swelling and superficial venous engorgement were observed. The patient was then admitted to Nanfang Hospital, where magnetic resonance imaging was performed, which identified symptoms of an abnormal periosteal reaction with bone erosion, indicating POS. The patient underwent a wide resection of the tumor and the histopathological examination confirmed the diagnosis of POS. No recurrence was identified at 9 months postoperatively. In conclusion, the present case report may result in increased awareness of the possibility of malignant bone tumors in a hereditary patient with osteotylus overgrowth following fracture surgery; in addition, the present case indicated a possible correlation between POS and MFS.

**Introduction**

Osteosarcoma is a frequent primary malignant bone tumor with predilection in children and adolescents (1), the oncogenesis of which has been reported to be partially associated with transforming growth factor β (TGF-β) (2). Periosteal osteosarcoma (POS), an intermediate-grade chondroblastic osteosarcoma arising from the surface of the long bones, accounts for <2% of all osteosarcomas (3,4). Previous studies have demonstrated that certain hereditary diseases including Rothmund-Thomson syndrome, Bloom syndrome and Li-Fraumeni syndrome may increase the risk of osteosarcoma (5,6).

Marfan’s syndrome (MFS), a rare autosomal dominant hereditary disorder of connective tissue, primarily affects the ocular, skeletal and cardiovascular systems, with high penetrance and variable phenotypes (7). MFS was reported to be associated with perturbations in TGF-β biology, which were commonly found to result from mutations in the fibrillin-1 gene (8,9). One previous study reported the simultaneous occurrence of MFS and osteosarcoma of the foot in a patient (10). However, it remains to be elucidated whether POS is associated with MFS.

The present study reported a case of POS and MFS co-occurring in a 6-year-old girl, the former of which induced a pathological femoral shaft fracture. The present report described the process of the disorders and reviewed the relevant literature.

**Case report**

**Overview.** A 6-year-old girl visited the clinic of Nanfang Hospital, Southern Medical University (Guangzhou, China) with aggravating swelling in the right thigh following two previous surgeries of internal fixation and implant removal, which were performed due to a femoral shaft fracture in her right leg. The present study was approved by medical ethics committee of Nanfang Hospital. Written informed consent from the patient's family was provided, and the patients' records were anonymized and de-identified prior to analysis.

**Medical history.** Abnormal symptoms were denied prior to the presentation of the fracture in the patient. A blood relationship between the patient's parents was also denied. The patient's
father had previously received a diagnosis of MFS; however, heredity disorders were not present in other members of the family.

Initial presentation. Subsequent to a fall during exercise, the patient presented with pain, swelling, deformity and disability in the right thigh. Radiograph images performed at a local hospital revealed a single fracture in the right femoral shaft. The patient was admitted and received fracture fixation surgery a week later. Symptomatic treatment and nutritional support were administered postoperatively. At 2 weeks post surgery, aggravated swelling was observed and the patient returned to the local hospital. X-ray examination revealed the formation of an extensive osteotylus in the affected site. The patient was readmitted and underwent removal of the implant 1 month following the initial surgery. Aggravated swelling appeared again, accompanied with superficial venous engorgement following the second surgery. The patient was then brought to Nanfang Hospital.

Medical examination. The patient was 123 cm in height and 24 kg in weight. Physical examination revealed a normal spinal curvature and a long slender neck. The upper to lower segment ratio was 0.82. Joint hypermobility was identified in the patient’s hands and fingers. Optic examination showed a slight impairment in both of the eyes. The circumference at 10 cm above patella of the right thigh was 52 cm, compared with 31 cm in the left thigh. In addition, tension blisters as well as superficial venous engorgement were observed. However, the sensation of the affected limb was normal.

Laboratory results demonstrated significantly increased serum levels of white blood cells (28.73x10^3/l; normal range, 3.5-9.5x10^3/l), C-reactive protein (81.1 mg/l; normal range, 0-5 mg/l) and alkaline phosphatase (976.4-1100 U/l; normal range, 50-400 U/l). However, the serum erythrocyte sedimentation rate (21 mm/l) was only slightly elevated compared with the upper value of normal range (20 mm/l). Radiograph images revealed extensive osteolytic destruction, asymmetrical periosteal reaction with Codman’s triangle and cortex thickening, which indicated the possibility of osteosarcoma. No X-ray abnormalities were identified in the hip or the knee (Fig. 1), nor in the chest. Magnetic resonance imaging (MRI) of right thigh revealed abnormal signals in T1 and T2-weighted images (Fig. 2A-C). Spinal MRI revealed a biconcave sign in the partial vertebral bodies (Fig. 2D). An electrocardiogram demonstrated normal sinus rhythms without other types of arrhythmia. In addition, an echocardiograph revealed normal sizes and motions of the ventricles, atria and valves. MFS was diagnosed according to the aforementioned clinical features and the associated family history.

Operative procedure and postoperative follow up. Osteosarcoma was suspected, based on the following factors: i) Extensive osteotylus was observed <1 month after fracture; ii) extensive osteolytic destruction, asymmetrical periosteal reaction with Codman’s triangle and cortex thickening were observed (Fig. 1); and iii) clinical symptoms and laboratory tests also indicated abnormalities, including tension blisters and superficial venous engorgement, as well as significantly increased serum levels of alkaline phosphatase, white blood cells and C-reactive protein. Thus, radical resection of the tumor was proposed according to the limb salvage requirement of the patient as well as the patient’s parents. Surgery was performed under general anesthesia. During surgery, the muscles around the femur were observed to have a fatty-like change and the aberrant bone grew widely around the bone shaft. The patient underwent thorough resection of the tumor and reconstruction. Resected tissues underwent histopathological and immunohistochemical examinations (Fig. 3A and B). Histopathological examination revealed marked chondroid differentiation with hypercellularity and prominent nuclear pleomorphism. Immunohistochemical examination revealed positive expression of CD99 (+), osteopontin (+, weakly), Ki-67 (+, 50%), p53 (+, individually) and S-100 (+), as well as negative expression of B cell lymphoma 2 (-). Outcomes of the above examinations confirmed the diagnosis of POS. Postoperative radiographs demonstrated that the primary tumor was resected completely and the intramedullary fixation of the femur was in place (Fig. 4).

Discussion

Osteosarcoma is one of the most frequent types of primary malignant bone tumors, accounting for ~15% of all bone tumors (11). In addition, the incidence rate of osteosarcoma arising from the surface of the long bones is markedly lower compared with those from other sites of the bone. Surface osteosarcomas are classified into three main types, including parosteal (juxtacortical), periosteal and high-grade osteosarcoma (12). POS was first reported by Ewing (13) in 1939; subsequently, in 1976, Unni et al (14) described the characteristics of POS pathology based on 23 patients. As
a type of intermediate-grade osteosarcoma, POS predominantly occurs in males and patients in the second decade of life (15,16). POS usually arises from the diaphysis or the meta-diaphyseal surface of the tibia and femur; in addition, POS is less aggressive and has a better prognosis compared with other frequent types of osteosarcoma (17,18). However, controversy still surrounds the treatment of this disease. The effect of chemotherapy treatment on the prognosis of POS patients remains indefinite (15), although it often demonstrates a promising clinical efficacy in the treatment of osteosarcoma. Grimer et al (15) reported the good prognosis of POS patients following only resection of the tumor. Thus, the case in the present study only received resection of the tumor without chemotherapy or radiotherapy. The role of the two adjunctive therapy methods in the treatment of POS requires further investigation.

MFS was first described by Antoine-Bernard Marfan in 1898. MFS is a rare autosomal dominantly inherited systemic connective tissue disorder with an estimated prevalence of 1-3 per 10,000 (19,20). The disease primarily affects the cardiovascular, skeletal and ocular systems, with skin, fascia, lung and adipose tissue occasionally involved (21). Diet et al (22) indicated that MFS was associated with the genetic defects in the chromosome loci $D_{15}S_{25}$ and $D_{15}S_{1}$. The
In conclusion, to the best of our knowledge, the present study was the first to report a case of simultaneous POS and MFS in a child. The case report identified the characteristics of POS and key points of the disease in the process of diagnosis and treatment. The present study may therefore increase the awareness of orthopedists on the possibility of a hereditary bone tumor in a hereditary patient with osteotylus overgrowth following fracture surgery. In addition, due to the simultaneous appearance of POS and MFS in the present case, it was suggested that further studies should be conducted to determine whether there is an association between the two rare disorders.
